(Received 16 September; revised 8 December; accepted 11 December 2019)

Abstract: Environmental pollution is a global problem, while bioremediation technology removes pollutants from the environment using microorganisms. This study aimed to investigate how a bioremediation process affected soil humification. In soil polluted with petroleum and its derivatives that was submitted to bioremediation, besides total petroleum hydrocarbons (TPH) and number of microorganisms, quantitative and qualitative changes of isolated humic acids were determined during the process. Bioremediation of 150 m³ of polluted soil lasted for 150 days. TPH decreased by 86.6 %, while the level of humic acids increased by 26.5 %. The elemental analysis showed the reduction of C and the H/C ratio and the increase of O and the O/C ratio of isolated humic acids during the process. The ratio of absorbances at 465 and 665 nm (E4/E6) also increased. Based on this and the Fourier-transform infrared spectra, it was shown that the humic acids isolated at the end of bioremediation were enriched with oxygen functional groups and aromatic structures. This study provides one of the first insights into the relationship between bioremediation and humification, as well as evidence of how hydrocarbon-degrading microorganisms have a significant influence on changes to humic acid structure during bioremediation.

Keywords: remediation; humification; total petroleum hydrocarbons.

INTRODUCTION

Petroleum and its derivatives are widely used in all domains of life. These compounds are extensively used as an energy sources for transportation, heating, and generating electricity.1 Pollution of soils, sediments, and waters by petroleum products is a substantial environmental problem.2,3 Pollution occurs due to accidental releases of hazardous waste during extraction, refining, transport, storage, and use of petroleum and its derivatives.4,5 However, the persistence of these compounds in the environment and their toxic effects can cause risks for

Bioremediation is a method of remediating petroleum pollution by applying selected microorganisms to polluted environmental substrates. These non-pathogenic microbes can degrade or transform toxic substances into harmless products. Bioremediation is low-cost and environmentally friendly remediation technology. This process is in harmony with the principles of sustainable development, and it has become widely used in recent decades.

During bioremediation of sites polluted with petroleum and its derivatives, substances similar to humic compounds are created. Wu and colleagues found similar sequential biological processes in composting. This is very important because humic substances (HSs) have a tremendously positive influence on soil quality.

HSs, heterogeneous organic macromolecules, are composed of a soil fraction soluble at all pHs – the fulvic acids (FAs), plus humic acids (HAs) that are soluble in neutral to alkaline pHs, and an insoluble fraction – humin. The essential components of HSs are HAs, and their study is important for understanding many processes in the environment. HAs are composed of quinone, phenolic, enolic, and carboxylic acid functional groups, and because of that, they have numerous uses. Scientific reports exist about soil and sediment humification are plentiful, but there is not enough data about the humification process during bioremediation and biodegradation. Since HAs are of vital importance for soil quality, their quantity should always be determined in bioremediation processes.

The aims of this study were to: 1) investigate the relationship between bioremediation and humification processes and to determine quantitative and qualitative changes of humic acids isolated during bioremediation of soil polluted with petroleum and its derivatives, and; 2) confirm the hypothesis that during bioremediation of soil polluted with petroleum hydrocarbons, evolution of humic acids will be stimulated to a higher degree than in non-polluted control soil.

EXPERIMENTAL

Experimental biopiles

The biopile for ex situ bioremediation consisted of 150 m³ soil polluted with petroleum and its derivatives. The control biopile (5 m³) consisted of non-polluted soil sampled from a location near the biopile. Biopiles geometry were a three-sided parallelepiped. Ratio of length, width and depth were 3.75:1:0.02, respectively. Both biopiles contained added: sawdust and wood chips to increase the water holding capacity, aeration, and also as an alternative source of carbon; BioSolve®CLEAR to increase dispersion of petroleum hydrocarbons in water, and to increase the contact surface between microorganisms and lipophilic pollutants; and manure from a poultry farm as a source of nitrogen and phosphorus for the biostimulation of the process. Finally, an enriched consortium of hydrocarbon-degrading microorganisms was added every two weeks to enhance microbial activity on both biopiles. Consortium were prepared as previously described. Dominant genera were Pseudomonas, Nocardia and Rhodococcus. This pilot bioremediation study lasted for 150 days.
Sampling

In order to collect the most representative samples, biopile soil samples were taken by the zig-zag sampling method\textsuperscript{17} with an Eijkelkamp auger soil sampler. Approximately 20 soil samples were then mixed and homogenized, thereby producing one composite biopile sample. A total of 4 composite samples for analysis were collected on each sampling day, at the beginning of bioremediation (designation S0), after 60 days (S60), after 120 days (S120) and after 150 days (S150). Control samples were taken at the same time from the control biopile.

**Determination of the number of microorganisms in the composite polluted biopile samples**

During bioremediation of polluted soil, the number and composition of microbial consortia were monitored. The number of total chemoorganotrophs (TC), \textit{i.e.} aerobic and facultative anaerobic, mesophile bacteria was determined on nutrient agar (15.0 g peptone I; 3.00 g meat extract; 15.00 g NaCl; 0.30 g K₂HPO₄; 18.0 g agar; 1 L deionized water; pH 7.30). Microorganisms that decompose hydrocarbons (HD) were determined on a mineral agar (1.00 g NH₄NO₃; 0.25 g CaHPO₄; 50.0 mL soil extract; 16.0 g agar; 1 L deionized water) supplemented with 2.00 g/L diesel D2 as a source of hydrocarbons.\textsuperscript{18} Malt agar was used to determine numbers of yeasts and molds (YM) (5.00 g peptone I; 30.0 g malt extract; 15.0 g agar; 1 L deionized water; pH 5.40). Composite biopile samples were homogenized and appropriate serial dilutions were plated on agar plates. All plates were incubated at 28 °C, for 48 h (TC and YM), and for 7 days (HD).\textsuperscript{19,20}

The presence of genera important for bioremediation process, \textit{Pseudomonas}, \textit{Nocardia} and \textit{Rhodococcus} were determined using the following media: \textit{Pseudomonas} was analyzed on \textit{Pseudomonas} isolation agar (20.0 g peptone I; 1.40 g MgCl₂×6H₂O; 10.0 g K₂SO₄; 25.0 mg irgasan; 13.6 g agar; 20.0 mL glycerol; 1 L distilled water).\textsuperscript{21} This selective medium includes irgasan, a broad-spectrum antimicrobial agent. Irgasan is not active against \textit{Pseudomonas} spp. and it was added after sterilization. \textit{Nocardia} and \textit{Rhodococcus} were analyzed on M3 agar (0.47 g KH₂PO₄; 0.73 g Na₂HPO₄; 0.01 g KNO₃; 0.29 g NaCl; 0.10 g MgSO₄×7H₂O; 0.02 g CaCO₃; 200 μg FeSO₄×7H₂O; 180 μg ZnSO₄×7H₂O; 20.0 μg MnSO₄×4H₂O; 0.20 g sodium propionate; 18.0 g agar; 1 L distilled water).\textsuperscript{22} After sterilization in autoclave, actidion (50.0 mg/L) and tiamin HCl (4.00 mg/L) were added. Actidion prevent growth of yeast and fungi. Tiamin HCl solution was sterilized through a filter with 0.45 μm pore.

**Determination of total petroleum hydrocarbons**

The total petroleum hydrocarbons (TPH) from both the polluted and nonpolluted biopiles were extracted\textsuperscript{23} and determined gravimetrically.\textsuperscript{24} Values were expressed as g kg\textsuperscript{-1} of dry weight (g kg\textsuperscript{-1} d.w.). A more detailed analysis of polluted biopile samples was conducted using a gas chromatograph (Agilent 7890A) with a flame ionization detector (FID). The HP-5 column was 30.0 m long, 0.32 mm in diameter and with 0.25 μm thickness of stationary phase. The flow rate of the hydrogen carrier gas was 2.00 mL min\textsuperscript{-1}. The starting temperature was 40.0 °C, the injector temperature was 250 °C, and the detector temperature was 300 °C, while the temperature ramped up at 4.00 °C min\textsuperscript{-1}. ChemStation, Agilent Technologies was used to process data. The analysis was performed in triplicate. The error in the method was about 5.70%.

**Determination of group composition of the composite polluted biopile samples**

Sokhlet extraction using Omnilab FoodALYT RS 60 was used to extract organic compounds from the composite polluted biopile samples (acetone:n-hexane 1:1, 130 mL, 24 h). After extraction, the samples were evaporated to dryness and submitted to fractional separation of organic substances based on the method previously described.\textsuperscript{25} In short, the extracts were
saponified with a solution of KOH in methanol and neutralized with 10 % hydrochloric acid. The products were dissolved in a mixture of dichloromethane and hexane and individually fractionated by column chromatography on alumina and silica gel into saturated hydrocarbons, aromatic hydrocarbons, polar fraction (alcohols and ketones) and fatty acids (the group composition). All fractions were eluted with different solvent mixtures. Values were expressed as g kg\(^{-1}\) d.w. The analysis was performed in triplicate. The results were processed by Microsoft Office Excel 2007 program.

**Extraction of humic acids**

Air-dried composite samples (40.0 g) from both the polluted and nonpolluted biopiles were separately mixed with NaOH/Na\(_2\)P\(_2\)O\(_7\) solution (200 mL). The mixtures were heated (boiling water bath with shaking, 2 h) and cooled to room temperature. The supernatant was separated by centrifugation (3000 rpm, 10 min) from each mixture, and HAs were precipitated from supernatant (with 6.0 M HCl to pH 1). After repeated centrifugation, supernatant was discarded. The HAs were purified according to International Humic Substance Society and Jednak et al. The analysis was performed in triplicate. The error in the method was about 4.50 %.

For quantitative and qualitative analysis of isolated humic acids from the composite polluted biopile samples following methods were used: elemental analysis, E4/E6 ratio and Fourier-transform infrared spectroscopy (FTIR).

**Elemental analysis of the humic acids isolated**

Contents of C, H, N and S in dry composite polluted biopile samples (dried at 105 °C, 2 h) were determined using a Vario EL II CHNS/O Elemental Analyser. Oxygen percentage was obtained by subsequent calculation (O content, % = 100 % - (C content, % + H content, % + N content, % + S content, %)).

**E4/E6 ratio of the humic acids isolated**

The E4/E6 ratios of the HAs isolated were calculated based on the ratio of absorbances at 465 and 665 nm. Absorbances of solutions (30.0 mg of HAs in 100 mL of 0.05 M NaHCO\(_3\)) were recorded using a UV-VIS Spectrophotometer (SHIMADZU, UV-1280). Fourier-transform infrared spectroscopy of the humic acids isolated

FTIR spectra of HAs were recorded on an FTIR spectrometer (Nicolet 6700 from Thermo Nicolet Corp., Madison, WI), in the wavelength range of 4000-400 cm\(^{-1}\). Samples were prepared before analysis (making pellets, which consist of isolated HAs and KBr).

**RESULTS AND DISCUSSION**

*Change in TPH content and number of microorganisms during bioremediation*

Gravimetric analysis showed the initial level of TPH (0 days) was 21.6 g kg\(^{-1}\) d.w. At the end of the study (after 150 days of bioremediation), TPH in the polluted biopile were reduced by 86.6 % (concentration at the end was 2.89 g kg\(^{-1}\) d.w.). Gas chromatograms of samples from the polluted biopile at the start and end of bioremediation are shown in Figure 1.
In the control biopile, there was a decrease of TPH from 0.36 to 0.34 g kg⁻¹ d.w. (TPH were reduced by 5.55 %). Fig. 2 shows the content of TPH and the numbers of hydrocarbon-degrading microorganisms during bioremediation.

Figure 2. Histogram shows content of TPH; line shows increase in the number of hydrocarbon-degrading microorganisms during bioremediation of polluted biopile (CFU – colony forming units).
After the initial biopile inoculation, a stable microbial community was formed (TC 1.05x10^6; HD 1.88x10^5; YM 2.00x10^3 CFU g\(^{-1}\)). At the end of the bioremediation of polluted soil, 79.2\% of the microorganisms were hydrocarbon degraders, so these formed the dominant microbial population (Table SI). In the microbial consortium, the presence of the genera *Nocardia*, *Pseudomonas* and *Rhodococcus* was confirmed. The literature shows these genera degrade petroleum and its derivatives with high efficiency.\(^1\)\(^-\)\(^3\)\(^,\)\(^5\)

Determination of group composition of the composite polluted biopile samples

Fractional separation of organic matter extracted from composite polluted biopile samples resulted in three classes of compounds (Fig. 3): saturated hydrocarbons, aromatic hydrocarbons, and the alcohols and ketones. The fatty acid fraction was not obtained.

![Figure 3. Aliphatic, aromatic, and polar (alcohols and ketones) fractions of composite polluted biopile samples during bioremediation.](image)

The concentration of the aliphatic fraction gradually decreased during the bioremediation process and at the end of the study was significantly lower than at the beginning (decreased from 8.28 to 2.80 g kg\(^{-1}\) d.w.). This fraction degraded the most, i.e. by 66.2 \%, which is in accordance with the literature.\(^16\) The concentration of the aromatic fraction was also reduced by the end of the bioremediation process, down from 7.68 to 4.50 g kg\(^{-1}\) d.w. This 41.4 \% reduction in the aromatic fraction could have been caused by microorganisms that used hydrocarbons as a source of carbon and energy or caused by microorganisms that used the aromatic fraction for the synthesis of polymeric,
humic-like substances.\textsuperscript{8,9} Alcohols and keto fraction decreased by 64.4\% (from 8.84 to 3.15 g kg\(^{-1}\) d.w.). Microorganisms with different rates of catabolism under varying conditions degrade various fraction of hydrocarbons.\textsuperscript{29,30} Rates of decrease (mg kg\(^{-1}\) per day) measured from start to the end of the process in the current study were 36.5 for the aliphatic, 21.2 for the aromatic, and 37.9 mg kg\(^{-1}\) per day for alcoholic and keto fraction. These results show that microorganisms consumed all the components of the hydrocarbon mixture. The significant reduction in the concentration of organic pollutants in the soil indicates successful bioremediation.

\textit{Quantitative and qualitative analysis of humic acids}

Elemental analysis and E4/E6 ratio of isolated HAs

At the beginning of bioremediation, the polluted biopile contained 2.16 \% HAs, while at the end of bioremediation, this biopile contained 2.94 \% HAs. The increase in the level of HAs during the bioremediation process was 26.5 \%. This indicates the processes of petroleum hydrocarbon biodegradation and humification occurred in parallel. Rates of humification were: 0-60 days, 38.3; 60-120 days, 55.0, 120-150 days, 73.3 mg kg\(^{-1}\) per day. In the control, non-polluted biopile, the HAs increased by 2.80 \% during the study.

Duration of treatment

For extracted HAs at the start of the process, elementary analysis showed the content of carbon and the calculated H/C ratio were higher than for HAs extracted at the end of the process (Table I). This could be attributed to an increase of aromatic structures during bioremediation.\textsuperscript{8,9,31} During bioreme-
diation, the oxygen content (increased from 23.23 to 27.97 %), calculated O/C ratio (increased from 0.28 to 0.35) and E4/E6 ratio (increased from 2.25 to 3.91) all increased, which indicates enrichment of HAs with oxygen functional groups. Table I also shows some comparative values extracted from published literature. They show significant variations in values, likely due to the diversity in the structure of humic acids.

FTIR spectra of isolated HAs

In the FTIR spectrum (Fig. S1 A-D), the following signals were present: aromatic C=C, C=O in carboxyl; ketone, quinone groups and amide (I) (the signal 1600-1660 cm\(^{-1}\)); aromatic C=C and amide II (the signal about 1508 cm\(^{-1}\)); OH of phenols, COO\(^{-}\) and amide II (signals between 1460 and 1370 cm\(^{-1}\)); aromatic ethers C–O–C and amide III (signals between 1260 and 1200 cm\(^{-1}\)).

</tbody>
</table>

Based on the intensity of the peaks in the FTIR spectra, transformation of HAs was observed during bioremediation. Changes were monitored by comparing the peak intensity and calculating the ratio of peaks 1654.1/2920.5 (aromatic C/aliphatic C) and 1654.1/2850.8 (aromatic C/aliphatic C) (Table II). The ratio of aromatic carbon to aliphatic carbon clearly increased during bioremediation. This indicates that HAs contained more aromatic structures at the end of bioremediation, which was also observed in our elementary analysis (Table I). This slight increase in the aromaticity of HAs could be caused by microorganisms which can transform aliphatics to aromatics and can form polymer humic compounds.

CONCLUSION

This study highlights the correlation between the bioremediation of soil polluted with petroleum and its derivatives and the process of humification. With the increasing duration of bioremediation, the level of TPH decreases. It should be emphasized that sawdust and wood chips, together with an important part of poultry manure (straw) are lignocellulosic wastes, the biodegradation of which produces humic substances. Based on our hypothesis, it is expected that the polluted soil after treatment will be cleaned from hydrocarbons while simultaneously, the content of humic substances will be increased. It is known that white and gray rot mushrooms degrade lignin and co-metabolic polycyclic aromatic hydrocarbons. However, we here confirm that microorganisms that are
hydrocarbon degraders also play a role in co-metabolic degradation of lignocellulosic material and increased humification of soil. Based on the results obtained, we conclude that not only did the amount of HAs increase, but their structures underwent profound changes. This was demonstrated by structural analyses, elemental analysis and FTIR. These results show that at the end of the bioremediation process, the aromaticity and level of oxygen groups in the HAs isolated both increased. In further work, the emphasis will be on detecting enzymes responsible for the degradation of aromatic compounds and co-metabolic production of humic acids.
